## 1 Abstract

In biomedical research, the outcome of longitudinal studies has been traditionally analyzed using the *repeated measures analysis of variance* (rm-ANOVA) or more recently, *linear mixed models* (LMEMs). Although LMEMs are less restrictive than rm-ANOVA in terms of correlation and missing observations, both methodologies share an assumption of linearity in the measured response, which results in biased estimates and unreliable inference when they are used to analyze data where the trends are non-linear. In contrast, generalized additive models (GAMs) relax the linearity assumption, and allow the data to determine the fit of the model while permitting missing observations and different correlation structures. Therefore, GAMs present an excellent choice to analyze non-linear longitudinal data in the context of biomedical research. This paper summarizes the limitations of rm-ANOVA and LMEMs and uses simulated data to visually show how both methods produce biased estimates when used on non-linear data. We also present the basic theory of GAMs, and use simulated data that follows trends reported in the biomedical literature to demonstrate how these models are implemented in R via the package *mgcv*, showing that GAMs are able to produce estimates that are consistent with the trends of non-linear data even if the case when missing observations exist. To make this work reproducible, the code and data used in this paper are available at: <https://github.com/aimundo/GAMs-biomedical-research>.

## 2 Background

Longitudinal studies are designed to repeatedly measure a variable of interest in a group (or groups) of subjects, with the intention of observing the evolution of effect across time rather than analyzing a single time point (e.g., a cross-sectional study). Biomedical research frequently uses longitudinal studies to analyze the evolution of a “treatment” effect across multiple time points; and in such studies the subjects of analysis range from animals (mice, rats, rabbits), to human patients, cells, or blood samples, among many others. Tumor response [1–4], antibody expression [5,6], and cell metabolism [7,8] are examples of the different situations where researchers have used longitudinal designs to study some physiological response. Because the frequency of the measurements in a longitudinal study is dependent on the biological phenomena of interest and the experimental design of the study, the frequency of such measurements can range from minute intervals to study a short-term response such as anesthesia effects in animals[9], to weekly measurements to analyze a mid-term response like the evolution of dermatitis symptoms in breast cancer patients [10], to monthly measurements to study a long-term response such as mouth opening following radiotherapy (RT) in neck cancer patients [11].

Traditionally, a “frequentist” or “classical” statistical paradigm is used in biomedical research to derive inferences from a longitudinal study. The frequentist paradigm regards probability as the limit of the expected outcome when an experiment is repeated a large number of times [12], and such view is applied

to the analysis of longitudinal data by assuming a null hypothesis under a statistical model that is often an *analysis of variance over repeated measures* (repeated measures ANOVA or rm-ANOVA). The rm-ANOVA model makes three key assumptions regarding longitudinal data: 1) linearity of the response across time, 2) constant correlation across same-subject measurements, and 3) observations from each subject are obtained at all time points through the study (a condition also known as *complete observations*) [13,14].

The expected linear behavior of the response through time is a key requisite in rm-ANOVA [15]. This “linearity assumption” in rm-ANOVA implies that the model is misspecified when the data does not follow a linear trend, which results in unreliable inference. In biomedical research, non-linear trends are the norm rather than the exception in longitudinal studies. A particular example of this non-linear behavior in longitudinal data arises in measurements of tumor response to chemo and/or radiotherapy in preclinical and clinical settings [1,8,16]. These studies have shown that the collected signal does not follow a linear trend over time, and presents extreme variability at different time points, making the fit of rm-ANOVA model inconsistent with the observed variation. Therefore, when rm-ANOVA is used to draw inference of such data the estimates are inevitably biased, because the model is only able to accommodate linear trends that fail to adequately represent the biological phenomenon of interest.

A *post hoc* analysis is often used in conjunction with rm-ANOVA to perform repeated comparisons to estimate a *p-value*, which in turn is used as a measure of significance. Although it is possible that a *post hoc* analysis of rm-ANOVA is able to find “significant” *p-values* ( $p < 0.05$ ) from non-linear data, the validity of such metric is dependent on how adequate the model fits the data. In other words, *p-values* are valid only if the model and the data have good agreement; if that is not the case, a “Type III” error (known as “model misspecification”) occurs [17]. For example, model misspecification will occur when a model that is only able to explain linear responses (such as rm-ANOVA) is fitted to data that follows a quadratic trend, thereby causing the resulting *p-values* and parameter estimates to be invalid [18].

Additionally, the *p-value* itself is highly variable, and multiple comparisons can inflate the false positivity rate (Type I error or  $\alpha$ ) [19,20], consequently biasing the conclusions of the study. Corrections exist to address the Type I error issue of multiple comparisons (such as Bonferroni [21]), but they in turn reduce statistical power ( $1 - \beta$ ) [22], and lead to increased Type II error (failing to reject the null hypothesis when the null hypothesis is false) [23,24]. Therefore, the tradeoff of *post hoc* comparisons in rm-ANOVA between Type I, II and III errors might be difficult to resolve in a biomedical longitudinal study where a delicate balance exists between statistical power and sample size.

On the other hand, the assumption of constant correlation in rm-ANOVA (often known as the *compound symmetry assumption*) is typically unreasonable because correlation between the measured responses often diminishes as the time interval between the observation increases [25]. Corrections can be made in rm-ANOVA in the absence of compound symmetry [26,27], but the effectiveness of the correction is limited by the size of the sample, the number of measurements [28], and group sizes [29]. In the case of biomedical research, where living subjects are frequently used, sample sizes are often not “large” due to ethical and budgetary reasons [30] which might cause the corrections for lack of compound symmetry to be ineffective.

Due to a variety of causes, the number of observations during a study can vary between all subjects. For example, in a clinical trial patients may voluntarily withdraw, whereas attrition due to injury or weight loss in preclinical animal studies is possible. It is even plausible that unexpected complications with equipment or supplies arise that prevent the researcher from collecting measurements at certain time points. In each of these missing data scenarios, the *complete observations* assumption of classical rm-ANOVA is violated. When incomplete observations occur, a rm-ANOVA model is fit by excluding all subjects with missing observations from the analysis [13]. This elimination of partially missing data from the analysis can result in increased costs if the desired statistical power is not met with the remaining observations, because it would be necessary to enroll more subjects. At the same time, if the excluded observations contain insightful information that is not used, their elimination from the analysis may limit the demonstration of significant differences between groups.

During the last decade, the biomedical community has started to recognize the limitations of rm-ANOVA in the analysis of longitudinal data. The recognition on the shortcomings of rm-ANOVA is exemplified by the use of linear mixed effects models (LMEMs) by certain groups to analyze longitudinal tumor response data

[8,16]. Briefly, LMEMs incorporate *fixed effects*, which correspond to the levels of experimental factors in the study (e.g., the different drug regimens in a clinical trial), and *random effects*, which account for random variation within the population (e.g., the individual-level differences not due to treatment such as weight or age). When compared to the traditional rm-ANOVA, LMEMs are more flexible as they can accommodate missing observations for multiple subjects and allow different modeling strategies for the variability within each measure in every subject [15]. However, LMEMs impose restrictions in the distribution of the errors of the random effects, which need to be normally distributed and independent [13,31]. And even more importantly, LMEMs also assume a linear relationship between the response and time [15], making them unsuitable to analyze non-linear data.

As the rm-ANOVA and the more flexible LMEM approaches make overly restrictive assumptions regarding the linearity of the response, there is a need for biomedical researchers to explore the use of additional statistical tools that allow the data (and not an assumption in trend) to determine the trend of the fitted model, to enable appropriate inference.

In this regard, generalized additive models (GAMs) present an alternative approach to analyze longitudinal data. Although not frequently used by the biomedical community, these semi-parametric models are customarily used in other fields to analyze longitudinal data. Examples of the use of GAMs include the analysis of temporal variations in geochemical and palaeoecological data [32–34], health-environment interactions [35] and the dynamics of government in political science [36]. There are several advantages of GAMs over LMEMs and rm-ANOVA models: 1) GAMs can fit a more flexible class of smooth responses that enable the data to dictate the trend in the fit of the model, 2) they can model non-constant correlation between repeated measurements [37] and 3) can easily accommodate missing observations. Therefore, GAMs can provide a more flexible statistical approach to analyze non-linear biomedical longitudinal data than LMEMs and rm-ANOVA.

The current advances in programming languages designed for statistical analysis (specifically R), have eased the computational implementation of traditional models such as rm-ANOVA and more complex approaches such as LMEMs and GAMs. In particular, R[38] has an extensive collection of documentation and functions to fit GAMs in the package *mgcv* [37,39] that not only speed up the initial stages of the analysis but also enable the use of advanced modeling structures (e.g. hierarchical models, confidence interval comparisons) without requiring advanced programming skills from the user. At the same time, R has many tools that simplify data simulation, an emerging strategy used to test statistical models [28]. Data simulation methods allow the researcher to create and explore different alternatives for analysis without collecting information in the field, reducing the time window between experiment design and its implementation, and simulation can be also used for power calculations and study design questions.

This work provides biomedical researchers with a clear understanding of the theory and the practice of using GAMs to analyze longitudinal data using by focusing on four areas. First, the limitations of LMEMs and rm-ANOVA regarding linearity of response, constant correlation structures and missing observations is explained in detail. Second, the key theoretical elements of GAMs are presented using clear and simple mathematical notation while explaining the context and interpretation of the equations. Third, using simulated data that reproduces patterns in previously reported studies [16] we illustrate the type of non-linear longitudinal data that often occurs in biomedical research. The simulated data experiments highlight the differences in inference between rm-ANOVA, LMEMs and GAMs on data similar to what is commonly observed in biomedical studies. Finally, reproducibility is emphasized by providing the code to generate the simulated data and the implementation of different models in R, in conjunction with a step-by-step guide demonstrating how to fit models of increasing complexity.

In summary, this work will allow biomedical researchers to identify when the use of GAMs instead of rm-ANOVA or LMEMs is appropriate to analyze longitudinal data, and provide guidance on the implementation of these models by improving the standards for reproducibility in biomedical research.

## 3 Challenges presented by longitudinal studies

### 3.1 The repeated measures ANOVA

The *repeated measures analysis of variance* (rm-ANOVA) is the standard statistical analysis for longitudinal data in biomedical research. This statistical methodology requires certain assumptions for the model to be valid. From a practical view, the assumptions can be divided in three areas: 1) linear relationship between covariates and response, 2) a constant correlation between measurements, and, 3) complete observations for all subjects. Each one of these assumptions is discussed below.

### 3.2 Linear relationship

#### 3.2.1 The repeated measures ANOVA case

In a longitudinal biomedical study, two or more groups of subjects (e.g., human subject, mice, samples) are subject to different treatments (e.g., a “treatment” group receives a novel drug or intervention vs. a “control” group that receives a placebo), and measurements from each subject within each group are collected at specific time points. The collected response is modeled with *fixed* components. The *fixed* component can be understood as a constant value in the response which the researcher is interested in measuring, i.e., the average effect of the novel drug/intervention in the “treatment” group.

Mathematically speaking, a rm-ANOVA model with an interaction can be written as:

$$y_{ijt} = \beta_0 + \beta_1 \times time_t + \beta_2 \times treatment_j + \beta_3 \times time_t \times treatment_j + \varepsilon_{ijt} \quad (1)$$

In this model  $y_{ijt}$  is the response for subject  $i$ , in treatment group  $j$  at time  $t$ , which can be decomposed in a mean value  $\beta_0$ , *fixed effects* of time ( $time_t$ ), treatment ( $treatment_j$ ) and their interaction  $time_t \times treatment_j$  which have linear slopes given by  $\beta_1, \beta_2$  and  $\beta_3$ , respectively. Independent errors  $\varepsilon_{tij}$  represent random variation not explained by the *fixed* effects, and are assumed to be  $\sim N(0, \sigma^2)$  (independently and identically normally distributed with mean zero and variance  $\sigma^2$ ). In a biomedical research context, suppose two treatments groups are used in a study (e.g., “placebo” vs. “novel drug” or “saline” vs. “chemotherapy”). Then, the group terms in Equation (1) can be written as below with  $treatment_j = 0$  representing the first treatment group (Group A) and  $treatment_j = 1$  representing the second treatment group (Group B). The linear models then can be expressed as

$$y_{ijt} = \begin{cases} \beta_0 + \beta_1 \times time_t + \varepsilon_{ijt} & \text{if Group A} \\ \beta_0 + \beta_2 + \beta_1 \times time_t + \beta_3 \times time_t + \varepsilon_{ijt} & \text{if Group B} \end{cases} \quad (2)$$

To further simplify the expression, substitute  $\widetilde{\beta}_0 = \beta_0 + \beta_2$  and  $\widetilde{\beta}_1 = \beta_1 + \beta_3$  in the equation for Group B. This substitution allows for a different intercept and slope for Groups A and B. The model is then written as

$$y_{ijt} = \begin{cases} \beta_0 + \beta_1 \times time_t + \varepsilon_{ijt} & \text{if Group A} \\ \widetilde{\beta}_0 + \widetilde{\beta}_1 \times time_t + \varepsilon_{ijt} & \text{if Group B} \end{cases} \quad (3)$$

Presenting the model in this manner makes clear that when treating different groups, an rm-ANOVA model is able to accommodate non-parallel lines in each case (different intercepts and slopes per group). In other words, the rm-ANOVA model “expects” a linear relationship between the covariates and the response, this means that either presented as Equation (1), Equation (2) or Equation (3), an rm-ANOVA model is only able to accommodate linear patterns in the data. If the data show non-linear behavior, the rm-ANOVA model will approximate this behavior with non-parallel lines.

### 3.2.2 The Linear Mixed Model Case

A linear mixed model (LMEM) is a class of statistical model that incorporates *fixed effects* to model the relationship between the covariates and the response, and *random effects* to model subject variability that is not the primary focus of the study but that might be important to distinguish [15,40]. A LMEM with interaction between time and treatment for a longitudinal study can be written as:

$$y_{ijt} = \beta_0 + \beta_1 \times \text{time}_t + \beta_2 \times \text{treatment}_j + \beta_3 \times \text{time}_t \times \text{treatment}_j + \mu_{ij} + \varepsilon_{ijt} \quad (4)$$

When Equation (1) and Equation (4) are compared, it is easily noticeable that LMEM and rm-ANOVA have the same construction regarding the *fixed effects* of time and treatment, but that the LMEM incorporates an additional source of variation (the term  $\mu_{ij}$ ). This term  $\mu_{ij}$  is the one that corresponds to the *random effect*, accounting for variability in each subject within each group. The *random* component can also be understood as used to model some “noise” in the response, but that is intended to be analyzed and disentangled from the “global noise” term  $\varepsilon_{ijt}$  from Equation (1).

For example, if the blood concentration of the drug is measured in certain subjects in the early hours of the morning while other subjects are measured in the afternoon, it is possible that the difference in the collection time introduces some “noise” in the data. As the name suggests, this “random” variability needs to be modeled as a variable rather than as a constant value. The *random effect*  $\mu_{ij}$  in Equation (4) is assumed to be  $\mu_{ij} \sim N(0, \sigma_\mu^2)$ . In essence, the *random effect* in a LMEM enables to fit models with different slopes at the subject-level [15]. However, the expected linear relationship of the covariates and the response in Equation (1) and in Equation (4) is essentially the same, representing a major limitation of LMEMs to fit a non-linear response.

### 3.3 Covariance in rm-ANOVA and LMEMs

In a longitudinal study there is an expected *covariance* between repeated measurements on the same subject, and because repeated measures occur in the subjects within each group, there is a *covariance* between measurements at each time point within each group. The *covariance matrix* (also known as the variance-covariance matrix) is a matrix that captures the variation between and within subjects in a longitudinal study [41] (For an in-depth analysis of the covariance matrix see [40,42]).

In the case of an rm-ANOVA analysis, it is typically assumed that the covariance matrix has a specific construction known as *compound symmetry* (also known as “sphericity” or “circularity”). Under this assumption, the between-subject variance and within-subject correlation are constant across time [26,42,43]. However, it has been shown that this condition is frequently not justified because the correlation between measurements tends to change over time [44]; and it is higher between consecutive measurements [13,25]. Although corrections can be made (such as Huynh-Feldt or Greenhouse-Geisser) [26,27] the effectiveness of each correction is limited because it depends on the size of the sample, the number of repeated measurements [28], and they are not robust if the group sizes are unbalanced [29]. Because biomedical longitudinal studies are often limited in sample size and can have an imbalanced design, the corrections required to use an rm-ANOVA model may not be able to provide a reasonable adjustment that makes the model valid.

In the case of LMEMs, one key advantage over rm-ANOVA is that they allow different structures for the variance-covariance matrix including exponential, autoregressive of order 1, rational quadratic and others [15]. Nevertheless, the analysis required to determine an appropriate variance-covariance structure for the data can be a challenging process by itself. Overall, the spherical assumption for rm-ANOVA may not capture the natural variations of the correlation in the data, and can bias the inferences from the analysis.

### 3.4 Missing observations

Missing observations are an issue that arises frequently in longitudinal studies. In biomedical research, this situation can be caused by reasons beyond the control of the investigator [45]. Dropout from patients

and attrition or injury in animals are among the reasons for missing observations. Statistically, missing information can be classified as *missing at random* (MAR), *missing completely at random* (MCAR), and *missing not at random* (MNAR) [42]. In a MAR scenario, the pattern of the missing information is related to some variable in the data, but it is not related to the variable of interest [46]. If the data are MCAR, this means that the missingness is completely unrelated to the collected information [47], and in the case of MNAR the missing values are dependent on their value.

An rm-ANOVA model assumes complete observations for all subjects, and therefore subjects with one or more missing observations are excluded from the analysis. This is inconvenient because the remaining subjects might not accurately represent the population, and statistical power is affected by this reduction in sample size [48]. In the case of LMEMs, inferences from the model are valid when missing observations in the data exist that are MAR or MCAR [40]. For example, if attrition occurs in all mice that had lower weights at the beginning of a chemotherapy response study, the missing data can be considered MAR because the missingness is unrelated to other variables of interest.

### 3.5 What do an rm-ANOVA and LMEM fit look like? A visual representation using simulated data

To visually demonstrate the limitations of rm-ANOVA and LMEMs for non-linear longitudinal data, this section presents a simulation experiment of a normally distributed response of two groups of 10 subjects each. An rm-ANOVA model (Equation (1)), and a LMEM (Equation (4)) are fitted to each group, using R[38] and the package *nlme*[49].

Briefly, two cases for the mean responses for each group are considered: in the first case, the mean response in each group is a linear function over time with different intercepts and slopes; a negative slope is used for Group 1 and a positive slope is used for Group 2 (Figure 1, A). In the second case, a second-degree polynomial (quadratic) function is used for the mean response per group: the quadratic function is concave down for Group 1 and it is concave up for Group 2 (Figure 1, C). In both the linear and quadratic simulated data, the groups start with the same mean value at the first time point. This is intentional in order to simulate the expected temporal evolution of some physiological quantity, which is typical in biomedical experiments.

Specifically, the rationale for the chosen linear and quadratic functions is the expectation that a measured response in two treatment groups is similar in the initial phase of the study, but as therapy progresses a divergence in the trend of the response indicates a treatment effect. In other words, Group 1 can be thought as a “Control” group and Group 2 as a “Treatment” group. From the mean response per group (linear or quadratic), the variability or “error” of individual responses within each group is simulated using a covariance matrix with compound symmetry (constant variance across time). Thus, the response per subject in both the linear and quadratic simulation corresponds to the mean response per group plus the error (Figure 1 B,D).

A more comprehensive exploration of the fit of rm-ANOVA and LMEMs for linear and non-linear longitudinal appears in Figure 5 and Figure 6 in the Appendix, where simulation with compound symmetry and independent errors (errors generated from a normal distribution that are not constant over time) and the plot of simulated errors, and fitted parameters is presented. We are aware that the simulated data used in this section present an extreme case that might not occur frequently in biomedical research, but they are used as a representation of the consequences of modeling non-linear data with a linear model such as rm-ANOVA or LMEMs. Of notice, Section 5 uses simulated data that does follow reported trends in the biomedical literature.

Figure 1: Simulated linear responses from two groups with correlated (top row) or independent (bottom row) errors using a LMEM and a rm-ANOVA model. A, D: Simulated data with known mean response (linear or quadratic, thin lines) and individual responses (points) showing the dispersion of the data. B,E: Estimates from the rm-ANOVA model for the mean group response (linear or quadratic). Points represent the original raw data. The rm-ANOVA model not only fails to pick the trend of the quadratic data but also assigns a global estimate that does not take between-subject variation. C, F: Estimates from the LMEM model in the linear and quadratic case. The LMEM incorporates a random effect for each subject, but this model and the rm-ANOVA model are unable to follow the trend of the data in each group and grossly bias the initial estimates for each group.

The simulation shows that the fit produced by the LMEM and the rm-ANOVA model is good for linear data, as the predictions for the mean response are reasonably close to the “truth” of the simulated data (Figure 1, B, E). When the linearity and compound symmetry assumptions are met, the model approximates well the individual trends and the mean trends by group.

However, consider the case when the data follows a non-linear trend, such as the simulated data in Figure 1, C. Here, the mean response per group was simulated using a quadratic function but errors, individual responses and the rm-ANOVA model were produced in the same manner as in (Figure 1 A and B). The mean response in the simulated data with quadratic behavior is changing in each group through the timeline, and the mean value is the same as the initial value by the fifth time point for each group. Fitting an rm-ANOVA model (1) or a LMEM (4) to this data produces the fit that appears in panels E and F in Figure 1.

A comparison of the fitted mean response of the LMEM and the rm-ANOVA model to the simulated data in Figure ((1, E, F) indicates that the models are not capturing the changes within each group. Specifically, note that the fitted mean response of both models (panel E, F) show that the change (increase for Treatment 1 or decrease for Treatment 2) in the response through time points 2 and 4 is not being captured. The LMEM

is only able to account for between-subject variation by providing different intercepts to each subject, but both models are not able to capture the fact that the initial values are the same in each group, and instead fit non-parallel lines that have initial values that are markedly different from the “true” initial values in each case (compare panel D with panels E and F). If such a change has important physiological implications, both rm-ANOVA and LMEMs omit it from the fitted mean response. Thus, even though the model correctly detects a divergence between treatment groups, the exact nature of this difference is not correctly identified, limiting valuable inferences from the data.

This section has used simulation to better convey the limitations of linearity and correlation in the response in non-linear data. Although the model fitted to the simulated data was an rm-ANOVA model, the main issue of an expected linear trend in the response is the same in the case of a LMEM. In the following section, we present generalized additive models (GAMs) as a data-driven alternative method to analyze longitudinal non-linear data.

## 4 GAMs as a special case of Generalized Linear Models

### 4.1 GAMs and Basis Functions

Generalized linear models (GLMs) are a family of models that fit a linear response function to data that do not have normally distributed errors[50]. In contrast, GAMs are a family of regression-based methods for estimating smoothly varying trends and are a broader class of models that contain the GLM family as a special case[34,37,51]. A GAM model can be written as:

$$y_{ijt} = \beta_0 + f(x_t | \beta_j) + \varepsilon_{ijt} \quad (5)$$

Where  $y_{ijt}$  is the response at time  $t$  of subject  $i$  in group  $j$ ,  $\beta_0$  is the expected value at time 0, the change of  $y_{ijt}$  over time is represented by the *smooth function*  $f(x_t | \beta_j)$  with inputs as the covariates  $x_t$  and parameters  $\beta_j$ , and  $\varepsilon_{ijt}$  represents the residual error.

In contrast to the linear functions used to model the relationship between the covariates and the response in rm-ANOVA or LMEM, GAMs use more flexible *smooth functions*. This approach is advantageous as it does not restrict the model to a linear relationship, although a GAM will estimate a linear relationship if the data is consistent with a linear response. One possible set of functions for  $f(x_t | \beta_j)$  that allow for non-linear responses are polynomials, but a major limitation is that polynomials create a “global” fit as they assume that the same relationship exists everywhere, which can cause problems with inference [36]. In particular, polynomial fits are known to show boundary effects because as  $t$  goes to  $\pm\infty$ ,  $f(x_t | \beta_j)$  goes to  $\pm\infty$  which is almost always unrealistic and causes bias at the endpoints of the time period.

The smooth functional relationship between the covariates and the response in GAMs is specified using a semi-parametric relationship that can be fit within the GLM framework, by using *basis function* expansions of the covariates and by estimating random coefficients associated with these basis functions. A *basis* is a set of functions that spans the mathematical space where the smooths that approximate  $f(x_t | \beta_j)$  exist [34]. For the linear model in Equation (1), the basis coefficients are  $\beta_1$ ,  $\beta_2$  and  $\beta_3$  and the basis vectors are  $time_t$ ,  $treatment_j$  and  $time_t \times treatment_j$ . The basis function then, is the combination of basis coefficients and basis vectors that map the possible relationship between the covariates and the response [52], which in the case of Equation (1) is restricted to a linear family of functions. In the case of Equation (5), the basis functions are  $f(x_t | \beta_j)$ , which means that the model allows for non-linear relationships among the covariates.

Splines (cubic, thin plate, etc.) are commonly used *basis functions*; a cubic spline is a smooth curve constructed from cubic polynomials joined together in a manner that enforces smoothness, and thin plate regression splines are an optimized version that work well with noisy data [34,37]. Splines have a long history in solving semi-parametric statistical problems and are often a default choice to fit GAMs as they are

a simple, flexible and powerful option to obtain smoothness [53]. Therefore, this data-driven flexibility in GAMs overcomes the limitation that occurs in LMEMs and rm-ANOVA when the data is non linear.

To further clarify the concept of basis functions and smooth functions, consider the simulated response for Group 1 in Figure (1, C). The simplest GAM model that can be used to estimate such response is that of a single smooth term for the time effect; i.e., a model that fits a smooth to the trend of the group through time. The timeline can be divided in equally spaced *knots*, each knot being a region where a different basis function will be used. Because there are six timepoints for this group, five knots can be used. The model with five knots to construct the smooth term means that it will have four basis functions (plus one that corresponds to the intercept). The choice of basis functions is set using default values in the package *mgcv* depending on the number of knots. In Panel A of Figure 2, the four basis functions (and the intercept) are shown. Each of the basis functions is composed of six different points (because there are six points on the timeline). To control the “wiggleness” of the fit, each of the basis functions of Panel A is weighted by multiplying it by a coefficient according to the matrix of Panel B. The parameter estimates are penalized where the penalty reduces the “wiggleness” of the smooth fit to prevent overfitting: A weak penalty estimate will result in wiggly functions whereas a strong penalty estimate provides evidence that a linear response is appropriate.

In other words, the six points of each basis are multiplied by the corresponding coefficient in panel B, thereby increasing or decreasing the original basis functions of Panel A. In Figure 2, Panel C shows the resulting weighted basis functions. Note that the magnitude of the weighting for basis function 1 has resulted in a decrease of its overall value (because the coefficient for that basis function is less than 1). On the other hand, basis function 3 has roughly doubled its value. Finally, the weighted basis functions are added at each timepoint to produce the smooth term. The resulting smooth term for the effect of *time* is shown in Panel D (orange line) along the simulated values per group, which appear as points.

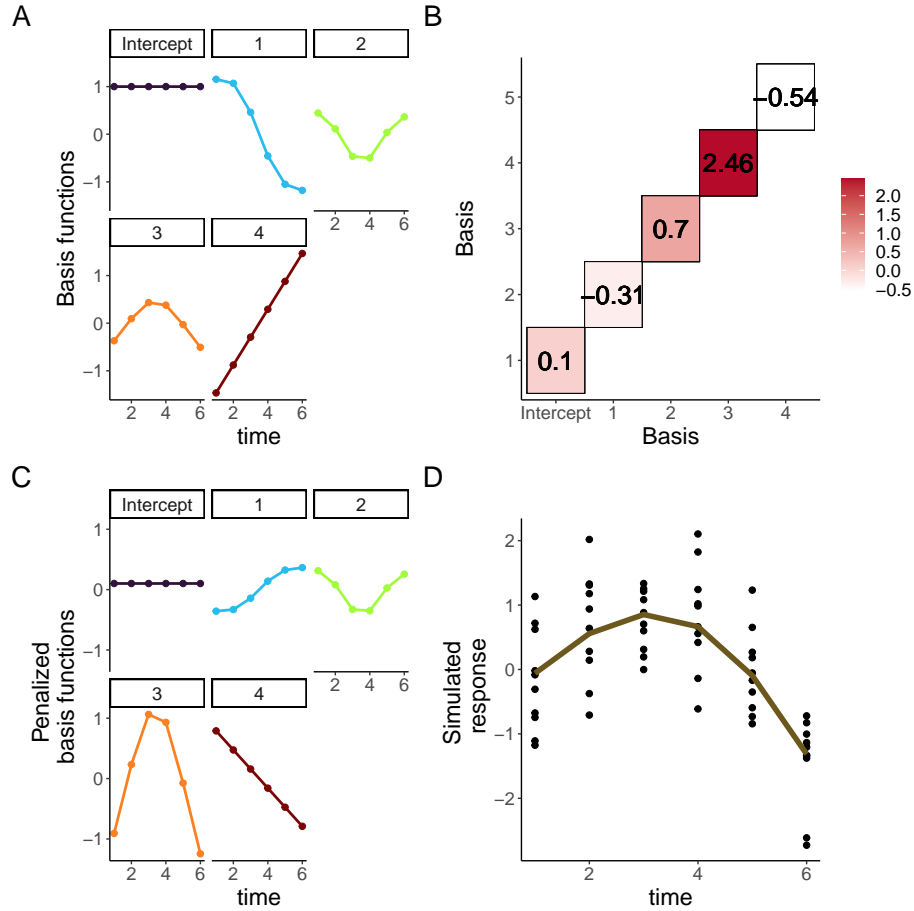

Figure 2: Basis functions for a single smoother for time with five knots. A: Basis functions for a single smoother for time for the simulated data of Group 1 from Figure 2, the intercept basis is not shown. B: Matrix for basis function weights. Each basis function is multiplied by a coefficient which can be positive or negative. The coefficient determines the overall effect of each basis in the final smoother. C: Weighted basis functions. Each of the four basis functions of panel A has been weighted by the corresponding coefficient shown in Panel B, note the corresponding increase (or decrease) of each basis. D: Smoother for time and original data points. The smoother (line) is the result of the sum of each penalized basis function at each time point, with simulated values for the group shown as points.

## 5 The analysis of longitudinal biomedical data using GAMs

The previous sections provided the basic framework to understand the GAM framework and how these models are more advantageous to analyze non-linear longitudinal data when compared to rm-ANOVA or LMEMs. This section will use simulation to present the practical implementation of GAMs for longitudinal biomedical data using R and the package `mgcv`. The code for the simulated data and figures, and a brief guide for model selection and diagnostics appear in the Appendix.

### 5.1 Simulated data

The simulated data is based on the reported longitudinal changes in oxygen saturation ( $\text{StO}_2$ ) in subcutaneous tumors that appear in Figure 3, C in [16]. In the paper, diffuse reflectance spectroscopy was used to quantify  $\text{StO}_2$  changes in both groups at the same time points (days 0, 2, 5, 7 and 10). In the “Treatment” group (chemotherapy) an increase in  $\text{StO}_2$  is observed through time, while a decrease is seen in the “Control” (saline) group. Following the reported trend, we simulated 10 normally distributed observations at each time point with a standard deviation (SD) of 10% (matching the SD in the original paper). The simulated and real data appear in Figure 3, A and the inlet, respectively.

### 5.2 An interaction GAM for longitudinal data

An interaction effect is typically the main interest in longitudinal biomedical data, as it takes into account treatment, time, and their combination. In a practical sense, when a GAM is implemented for longitudinal data, a smooth can be added to the model for the *time* effect to account for the repeated measures over time. Although specific methods of how GAMs model correlation structures is a topic beyond the scope of this paper, it suffices to say that GAMs are flexible and can handle correlation structures beyond compound symmetry. A detailed description on basis functions and correlations can be found in [52].

For the data in Figure 3, A the main effect of interest is how  $\text{StO}_2$  changes over time for each treatment. To estimate this, the model incorporates independent smooths for *Group* and *Day*, respectively. The main thing to consider is that model syntax accounts for the fact that one of the variables is numeric (*Day*) and the other is a factor (*Group*). Because the smooths are centered at 0, the factor variable needs to be specified as a parametric term in order to identify any differences between the groups. Using R and the package `mgcv` the model syntax is:

```
m1 <- gam(StO2_sim ~ Group + s(Day, by=Group, k=5), method='REML', data=dat_sim)
```

This syntax specifies that `m1` will store the model, and that the change in the simulated oxygen saturation (`StO2_sim`) is modeled using independent smooths for `Group` and `Day` (the parenthesis preceded by `s`) using 5 knots. The smooth is constructed by default using thin plate regression splines, but other splines can be used if desired, including Gaussian process smooths [34]. The parametric term `Group` is added to quantify differences in the effect of treatment between groups, and the `method` chosen to estimate the smoothing parameters is the restricted maximum likelihood (REML) [37]. When the smooths are plotted over the raw data, it is clear that the model has been able to capture the trend of the change of  $\text{StO}_2$  for each group across time (Figure 3,B). Model diagnostics can be obtained using the `gam.check` function, and the function `appraise` from the package `gratia` [54]. A guide for model selection and diagnostics is in the Appendix, and an in-depth analysis can be found in [37] and [55].

One question that might arise at this point is “what is the fit that an rm-ANOVA model produces for the simulated data?” The rm-ANOVA model, which corresponds to Equation (1) is presented in Figure 3, C. This is a typical case of model misspecification: The slopes of each group are different, which would lead to a *p-value* indicating significance for the treatment and time effects, but the model is not capturing the changes that occur at days 2 and between days 5 and 7, whereas the GAM model is able to do so (Figure 3, B) .

381 Because GAMs do not require equally-spaced or complete observations for all subjects, they are advantageous  
 382 to analyze longitudinal data where missingness exists. The rationale behind this is that GAMs are able to  
 383 pick the trend in the data even when some observations are missing. However, this usually causes the  
 384 resulting smooths to have wider confidence intervals and less ability to pick certain trends. Consider the  
 385 simulated  $\text{StO}_2$  values from Figure (3, B). If 40% of the total observations are randomly deleted and the  
 386 same interaction GAM fitted for the complete dataset is used, the resulting smooths are still able to show a  
 387 different trend for each group, but it can be seen that the smooths overlap during the first 3 days because  
 388 with less data points, the trend is less pronounced than in the full dataset (3, D). Although the confidence  
 389 intervals have increased for both smooths, the model still shows different trends with as little as 4 observations  
 390 per group at certain time points.

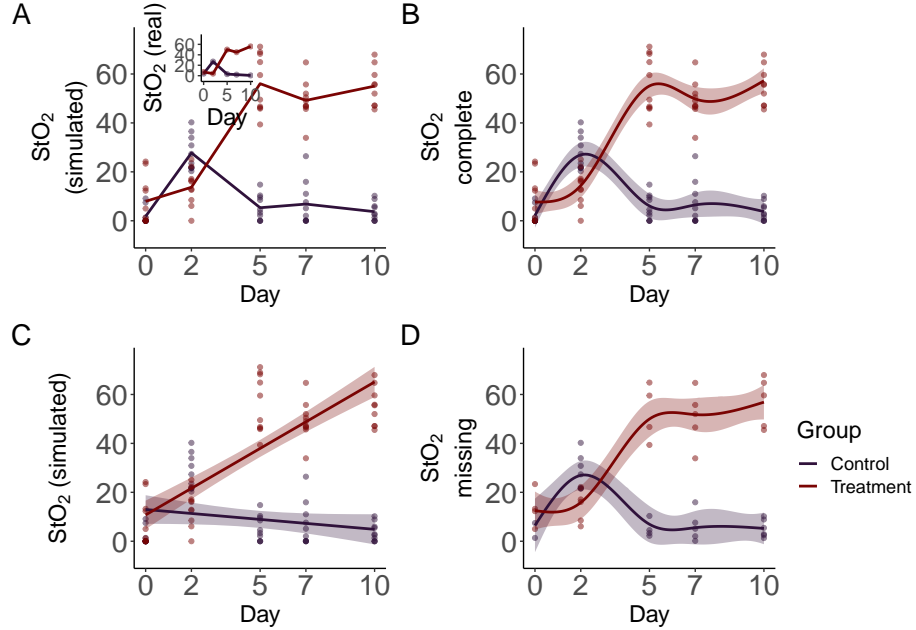

Figure 3: Simulated data and smooths for oxygen saturation in tumors. A: Simulated data that follows previously reported trends (inset) in tumors under chemotherapy (Treatment) or saline (Control) treatment. Simulated data is from a normal distribution with standard deviation of 10% with 10 observations per time point. Lines indicate mean oxygen saturation B: Smooths from the GAM model for the full simulated data with interaction of Group and Treatment. Lines represent trends for each group, shaded regions are 95% confidence intervals. C: rm-ANOVA model for the simulated data, the model does not capture the changes in each group over time. D: Smooths for the GAM model for the simulated data with 40% of its observations missing. Lines represent trends for each group, shaded regions are 95% confidence intervals.

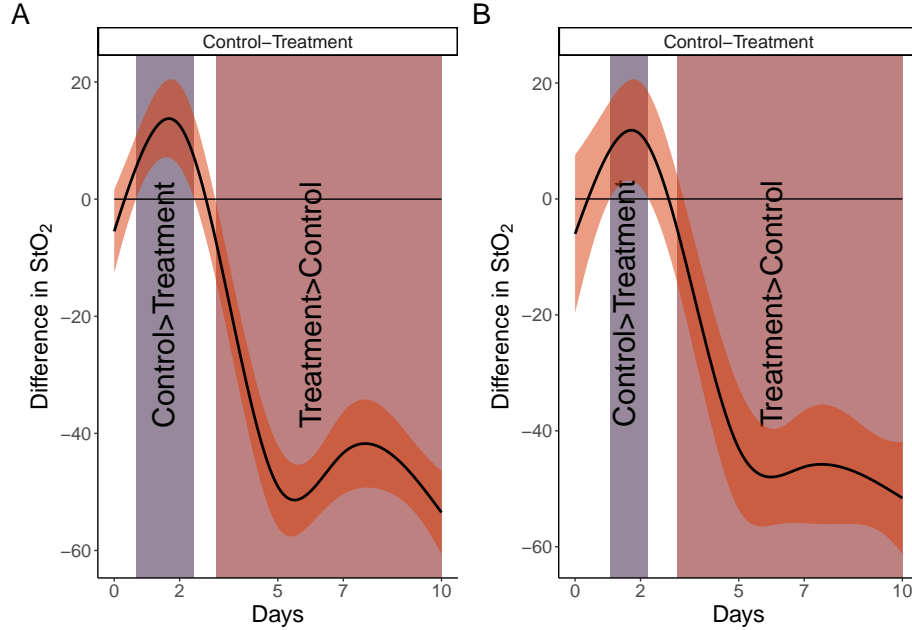

Figure 4: Pairwise comparisons for smooth terms. A: Pairwise comparisons for the full dataset. B: Pairwise comparisons for the dataset with missing observations. Significant differences exist where the interval does not cover 0. In both cases the effect of treatment is significant after day 3.

### 5.3 Determination of significance in GAMs for longitudinal data

At the core of a biomedical longitudinal study lies the question of a significant difference between the effect of two or more treatments in different groups. Whereas in *rm*-ANOVA a *post-hoc* analysis is required to answer such question by calculating some *p-values* after multiple comparisons, GAMs can use a different approach to estimate significance. In essence, the idea behind the estimation of significance in GAMs across different treatment groups is that if the *difference* between the empirical Bayesian confidence intervals of the fitted smooths for such groups is non-zero, then a significant difference exists at that time point(s). The absence of a *p-value* in this case might seem odd, but the empirical Bayesian confidence interval interpretation can be conceptualized in the following manner: Different trends in each group are an indication of an effect by the treatment. This is what happens for the simulated data in Figure 3, A where the chemotherapy causes  $\text{StO}_2$  to increase over time.

With this expectation of different trends in each group, computing the difference between the trends will identify if the observed change is significant. The difference between groups with similar trends is likely to yield zero, which would indicate that the treatment is not causing a change in the response in one of the groups (assuming the other group is a Control or Reference group).

Consider the calculation of pairwise differences for the smooths in Figure 3, B and D. Figure 4, shows the comparison between each treatment group for the full and missing datasets. Here, the “Control” group is used as the reference to which “Treatment” group is being compared. Of notice, the pairwise comparison has been set on the response scale (see Appendix for code details), because otherwise the comparison appears shifted and is not intuitively easy to relate to the original data.

With this correction in mind, the shaded regions over the confidence interval (where it does not cover 0) indicate the time interval where each group has a higher effect than the other. Notice that the shaded region between days 0 and  $\approx 2$  for the full dataset indicates that through that time, the “Control” group has higher  $\text{StO}_2$ , but as therapy progresses the effect is reversed and by  $\approx 3$  day it is the “Treatment” group the one that has greater  $\text{StO}_2$ . This would suggest that the effect of chemotherapy in the “Treatment” group becomes

significant after day 3 for the model used. Moreover, notice that although there is no actual measurement at day 3, the model is capable of providing an estimate of when the shift in  $\text{StO}_2$  occurs.

On the data with missing observations (Figure 3, D), the confidence intervals of the smooths overlap between days 0 and 3. Consequently, the smooth pairwise comparison (Figure 4, B) shows that there is not a significant difference between the groups during that period, but is still able to pick the change on day 3 as the full dataset smooth pairwise comparison.

In a sense, the pairwise smooth comparison is more informative than a *post-hoc p-value*. For biomedical studies, the smooth comparison is able to provide an estimate of *when* and by *how much* a biological process becomes significant. This is advantageous because it can help researchers gain insight on metabolic changes and other biological processes that can be worth examining, and can help refine the experimental design of future studies in order to obtain measurements at time points where a significant change might be expected.

## 6 Discussion

Biomedical longitudinal non-linear data is particularly challenging to analyze due to the likelihood of missing observations and different correlation structures in the data, which limit the use of rm-ANOVA. Although LMEMs have started to replace rm-ANOVA as the choice to analyze biomedical data, both methods yield biased estimates when they are used to fit non-linear data as we have visually demonstrated in Section 3.5. This “model misspecification” error, also is known as a “Type III” error [17] is particularly important because although the *p-value* is the common measure of statistical significance, the validity of its interpretation is determined by the agreement of the data and the model. Guidelines for statistical reporting in biomedical journals exist (the SAMPL guidelines) [56] but they have not been widely adopted and in the case of longitudinal data, we consider that researchers would benefit from reporting a visual assessment of the correspondence between the model fit and the data, instead of merely relying on a  $R^2$  value.

In this paper we have presented GAMs as a suitable method to analyze non-linear longitudinal data. It is interesting to note that although GAMs are a well established method to analyze temporal data in different fields (among which are palaeoecology, geochemistry, and ecology) [33,52] they are not routinely used in biomedical research despite an early publication from Hastie and Tibshirani that demonstrated their use in medical research [57]. This is possibly due to the fact that the theory behind GAMs can seem very different from that of rm-ANOVA and LMEMs, but the purpose of Section 4 is to demonstrate that at its core the theory quite simple: Instead of using a linear relationship to model the response (as rm-ANOVA and LMEMs do), GAMs use basis functions to build smooths that are capable of following non-linear trends in the data.

However, from a practical standpoint is equally important to demonstrate how GAMs are computationally implemented. We have provided an example on how GAMs can be fitted using simulated data that follows trends reported in biomedical literature [16] using R and the package *mgcv*[37] in Section 5, while a basic workflow for model selection is in the Appendix. One of the features of GAMs is that they go beyond a mere *p-value* to indicate differences between groups, and in turn provide a time-based estimate of shifts in the response that can be directly tied to biological values as the pairwise smooth comparisons in Figure 4 indicate. The model is therefore able to provide an estimate of significant change between the groups at time points where data was not directly measured even with missing data exists ( $\approx$  day 3 in Figure 4 A, B), which can be used by researchers as feedback on experiment design and to further evaluate important biological changes in future studies.

We have used R as the software of choice for this paper because not only provides a fully developed environment to fit GAMs, but also eases simulation (which is becoming increasingly used for exploratory statistical analysis and power calculations) and provides powerful and convenient methods of visualization, which are key aspects that biomedical researchers might need to consider to make their work reproducible. In this regard, reproducibility is still an issue in biomedical research [58,59], but it is becoming apparent that what other disciplines have experienced in this aspect is likely to impact sooner rather than later this field. Researchers need to plan on how they will make their data, code, and any other materials open and accessible as more journals and funding agencies recognize the importance and benefits of open science in biomedical

research. We have made all the data and code used in this paper accessible, and we hope that this will encourage other researchers to do the same with future projects.

## 7 Conclusion

We have presented GAMs as a method to analyze longitudinal biomedical data. Future directions of this work will include simulation-based estimations of statistical power using GAMs, as well as demonstrating the prediction capabilities of these models using large datasets. By making the data and code used in this paper accessible, we hope to address the need of creating and sharing reproducible work in biomedical research.

## A Code for Manuscript data

This section presents the code used to generate figures, models and simulated data from Sections 3 and 4 from the main manuscript.

## A.1 Compound symmetry and independent errors in linear and quadratic responses

This section simulated linear and quadratic data in the same manner as in Section 3.5. The linear simulations using Figure 5 show in panels A and D the simulated mean responses and individual data points. Panels C and G show a visual interpretation of “correlation” in the responses: In panel C, subjects that have a value of the random error  $\varepsilon$  either above or below the mean group response are more likely to have other observations that follow the same trajectory, thereby demonstrating correlation in the response. In panel G, because the errors are independent, there is no expectation that responses are likely to follow a similar pattern. Panels D and H show the predictions from the rm-ANOVA model.

The following code produces a more comprehensive exploration of Figure 1 in the main manuscript.

---

```
#####Section for calculations#####

## Example with linear response

#This function simulates data using a linear or quadratic mean response
  and each with correlated
#or uncorrelated errors. Each group has a different slope/concavity.
example <- function(n_time = 6, #number of time points
                    fun_type = "linear", #type of response
                    error_type = "correlated") {

  if (!(fun_type %in% c("linear", "quadratic")))
    stop('fun_type must be either "linear", or "quadratic"')
  if (!(error_type %in% c("correlated", "independent")))
    stop('fun_type must be either "correlated", or "independent"')

  x <- seq(1,6, length.out = n_time)

  #Create mean response matrix: linear or quadratic
  mu <- matrix(0, length(x), 2)
  # linear response
  if (fun_type == "linear") {
    mu[, 1] <- - (0.25*x)+2
    mu[, 2] <- 0.25*x+2
  } else {
    # quadratic response (non-linear)

    mu[, 1] <- -(0.25 * x^2) +1.5*x-1.25
    mu[, 2] <- (0.25 * x^2) -1.5*x+1.25
  }

  #create an array where individual observations per each time point for
    each group are to be stored. Currently using 10 observations per
    timepoint
  y <- array(0, dim = c(length(x), 2, 10))

  #Create array to store the "errors" for each group at each timepoint.
    The "errors" are the
  #between-group variability in the response.
  errors <- array(0, dim = c(length(x), 2, 10))
```

```

650 #create an array where 10 observations per each time point for each
651     group are to be stored
652
653 #The following cycles create independent or correlated responses. To
654     each value of mu (mean response per group) a randomly generated error
655     (correlated or uncorrelated) is added and thus the individual
656     response is created.
657 if (error_type == "independent") {
658     ## independent errors

```

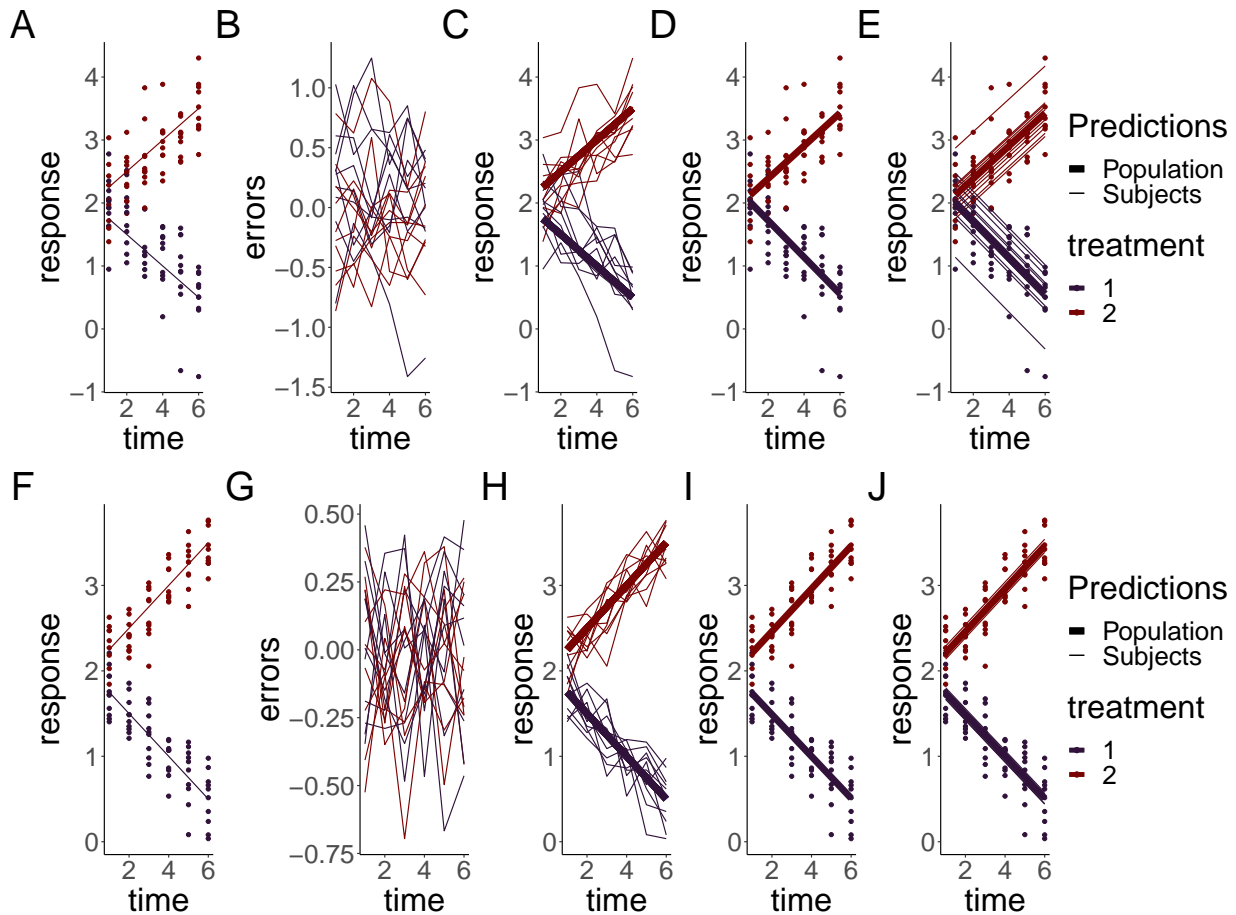

Figure 5: Simulated linear responses from two groups with correlated (top row) or independent (bottom row) errors using a rm-ANOVA model and a LMEM. A, F: Simulated data with known mean response and individual responses (points) showing the dispersion of the data. B, G: Generated errors showing the difference in the behavior of correlated and independent errors. C, H: Simulated data with thin lines representing individual trajectories. D, I: Estimations from the rm-ANOVA model for the mean group response. E, J: Estimations from the LMEM for the mean group response and individual responses (thin lines). In all panels, thick lines are the predicted mean response per group, thin lines are the random effects for each subject and points represent the original raw data. Both rm-ANOVA and the LMEM are able to capture the trend of the data.

882 For the quadratic response case, Figure 6 shows the simulated responses using compound symmetry and  
 883 independent errors.

Figure 6: Simulated quadratic responses from two groups with correlated (top row) or independent (bottom row) errors using a rm-ANOVA model and a LMEM. A, F: Simulated data with known mean response and individual responses (points) showing the dispersion of the data. B, G: Generated errors showing the difference in the behavior of correlated and independent errors. C, H: Simulated data with thin lines representing individual trajectories. D, I: Estimations from the rm-ANOVA model for the mean group response. E, J: Estimations from the LMEM for the mean group response and individual responses (thin lines). In all panels, thick lines are the predicted mean response per group, thin lines are the random effects for each subject and points represent the original raw data. Both rm-ANOVA and the LMEM are not able to capture the changes in each group over time.

## 884 A.2 Basis functions and GAMs

885 This code produces Figure 2 from the main manuscript. Briefly, a non-linear (quadratic) response is simulated  
 886 a gam model is fitted and the basis are extracted in order to explain how the smooth is constructed. The  
 887 code for data simulation is used again here for the sake of keeping the same structure, although the data  
 888 can be simulated in a more simple fashion.

```
889 #generate the response: the same initial procedure from the previous
890 section to simulate
891
892 #the response
893 set.seed(1)
894 n_time = 6
```

```

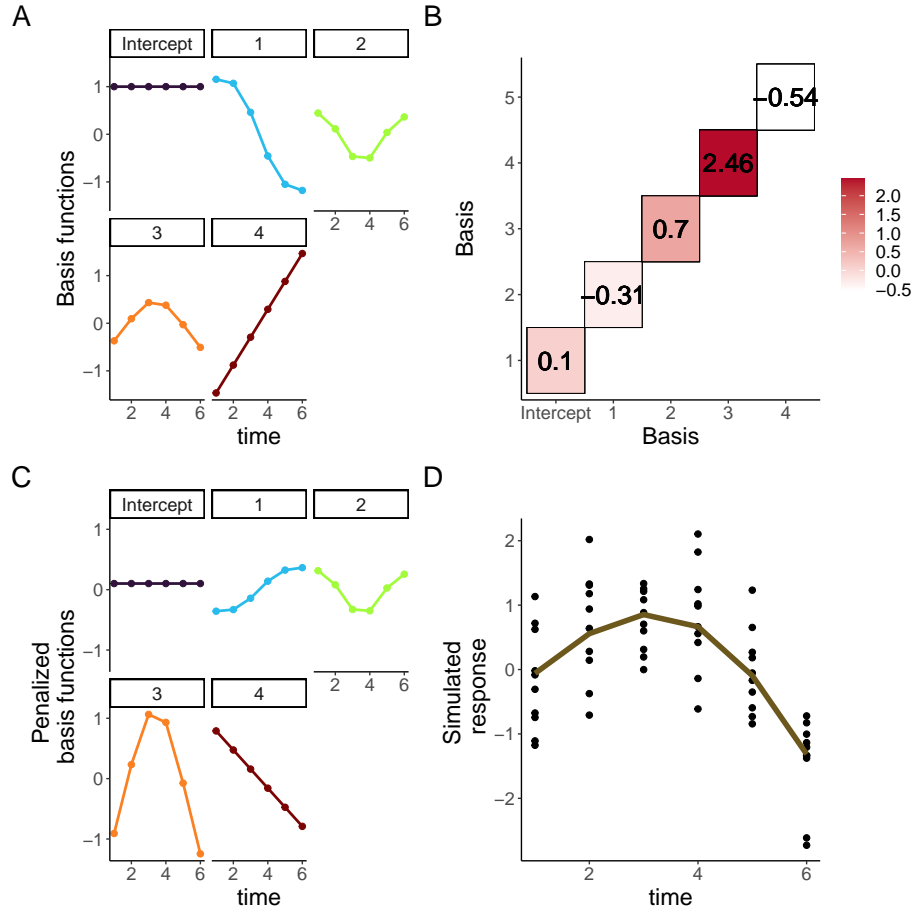

Figure 7: Basis functions for a single smoother for time with five knots. A: Basis functions for a single smoother for time for the simulated data of Group 1 from Figure 2, the intercept basis is not shown. B: Matrix for basis function weights. Each basis function is multiplied by a coefficient which can be positive or negative. The coefficient determines the overall effect of each basis in the final smoother. C: Weighted basis functions. Each of the four basis functions of panel A has been weighted by the corresponding coefficient shown in Panel B, note the corresponding increase (or decrease) of each basis. D: Smoother for time and original data points. The smoother (line) is the result of the sum of each penalized basis function at each time point, with simulated values for the group shown as points.

## B Longitudinal biomedical data simulation and GAMs

This section describes how to fit GAMs to longitudinal data using simulated data. First, data is simulated according to Section 5, where reported data of oxygen saturation ( $\text{StO}_2$ ) in tumors under either chemotherapy or saline control is used as a starting point to generate individual responses in each group.

## 1149 B.1 A basic Workflow for GAMs

1150 This section shows a basic workflow to fit a series of increasingly complex GAMs to the simulated data from  
 1151 the previous section. Graphical and parameter diagnostics for goodness of fit are discussed, as well as model  
 1152 comparison via AIC (Aikake Information Criterion).

### 1153 B.1.1 First model

1154 The first model fitted to the data is one that only accounts for different smooths by day. The model syntax  
 1155 specifies that `gam_00` is the object that will contain all the model information, and that the model attempts  
 1156 to explain changes in `StO2_sim` (simulated StO<sub>2</sub>) using a smooth per `Day`. The model will use 5 knots (`k=5`)  
 1157 for the smooth. The smooth is constructed by default using thin plate regression splines. The smoothing  
 1158 parameter estimation method used is the restricted maximum likelihood (REML).

```

1159 gam_00<-gam(StO2_sim ~ s(Day, k = 5),
1160            method='REML',
1161            data = dat_sim)
1162
1163

```

---

1164 To obtain model diagnostics, two methodologies are to be used: 1) graphical diagnostics, and 2) a model  
 1165 check. In the first case, the functions `appraise` and `draw` from the package *gratia* can be used to obtain  
 1166 a single output with all the graphical diagnostics. For model check, the functions `gam.check` and `summary`  
 1167 from *mgcv* provide detailed information about the model fit and its parameters.

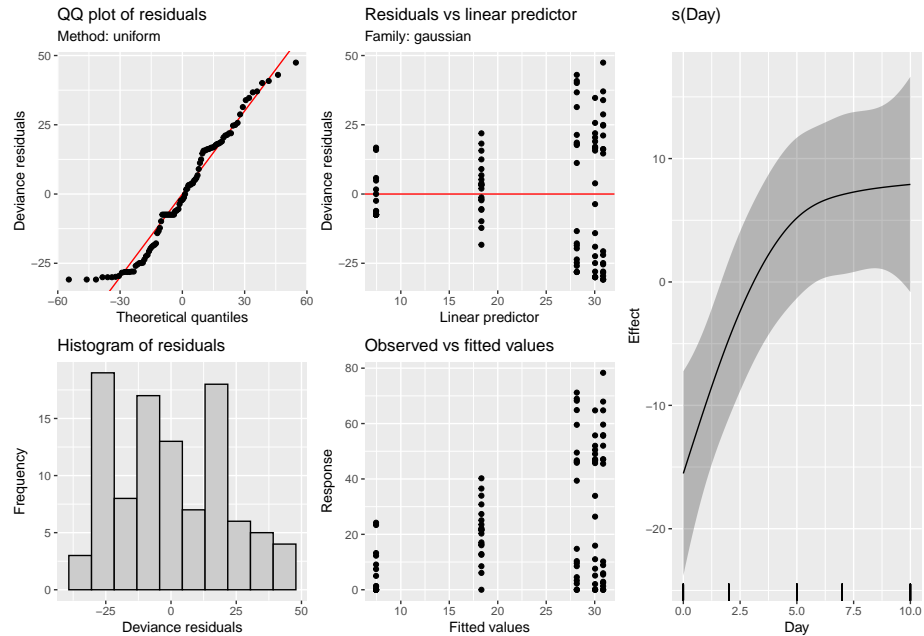

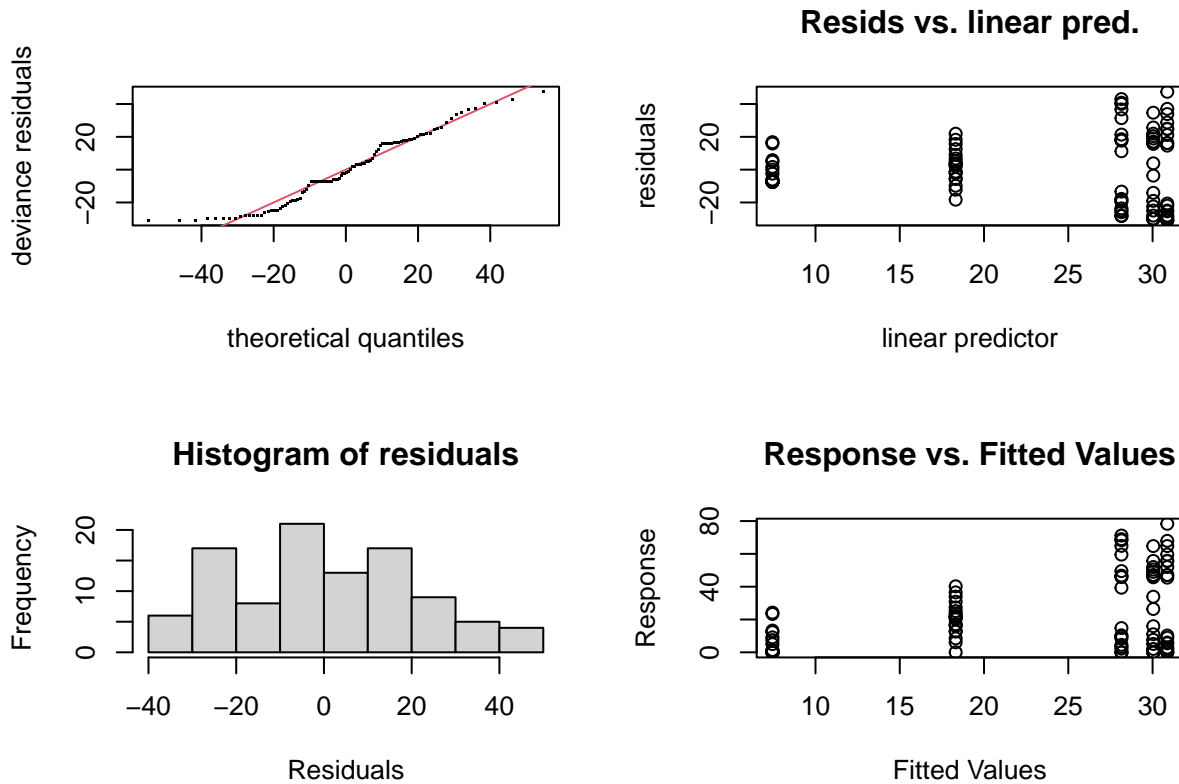

Figure 8: Graphical diagnostics for the first GAM model. Left: Graphical diagnostics provided by the function `appraise` from the package *gratia*. Right: Fitted smooth for the model, provided by the function `draw`.

**B.1.1.1 Graphical diagnostics** From the output of the function `appraise` in Figure 8, the major indicators of concern about the model are the QQ plot of residuals and the histogram of residuals. The QQ plot shows that the errors are not reasonably located along the  $45^\circ$  line (which indicates normality), as there are multiple points that deviate from the trend, specially in the tails. The histogram also shows that the variation (residuals) is not following the assumption of a normal distribution.

The `draw` function permits to plot the smooths as `ggplot2` objects, which eases subsequent manipulation, if desired. Because model `gam_00` specifies only one smooth for the time covariate (Day), the plot only contains only one smooth. Note that the smooth shows an almost linear profile.

**B.1.1.2 Model check**

```
#need to add figure number and caption
gam.check(gam_00)
```

```

1222 ## -REML = 444.01   Scale est. = 450.66      n = 100
1223

```

1224 Special attention must be paid to the ‘k-index’ from `gam.check`. This parameter indicates if the basis  
1225 dimension of the smooth is adequate, i.e., it checks that the basis used to create the smooth are adequate  
1226 to capture the trends in the data. If the model is not adequately capturing the trends in the data, this is  
1227 indicated by a low k-index value ( $<1$ ). From the output, it can be seen that the k-index is 0.36, which  
1228 indicates that the model is not capturing the variability in the data. The `edf` (effective degrees of freedom)  
1229 is an indicator of the complexity of the smooth. Here the complexity of the smooth is comparable to that of  
1230 a 4th degree polynomial.

1231 From the `summary` function, information about the assumed distribution of the errors (Gaussian in this  
1232 case) and the link function can be obtained. The link function is ‘identity’ as the model does not make  
1233 any transformation on the predictors. The ‘significance of smooth terms’ *p-value* indicates if each smooth  
1234 is adding significance to the model. Here, the *p-value* is low but we have seen that there are issues with  
1235 the model from the previous outputs. Finally, the ‘deviance explained’ indicates how much of the data the  
1236 model is able to capture, which in this case corresponds to  $\approx 17\%$ .

## 1237 B.1.2 Second model

1238 The major flaw of `gam_00` is that this model is not taking into account the fact that the data is nested in  
1239 groups. The next iteration is a model where a different smooth of time (Day) is assigned for each group  
1240 using `by=Group` in the model syntax.

```

1241 gam_01<-gam(St02_sim ~ s(Day, by=Group,k = 5),
1242             method='REML',
1243             data = dat_sim)
1244
1245 gam.check(gam_01)
1246
1247

```

```

1248
1249
1250 ##

1292 ## -REML = 423.39   Scale est. = 280.88      n = 100
1293

```

1294 Diagnostics for this model indicate that the k-index is still below 1 (0.43 from `gam.check`), and that the  
1295 residuals are still not following a normal distribution (Figure 9). Moreover, the smooths (plotted via the  
1296 `draw()` function) appear with a fairly linear profile, which indicates they are still not capturing the trends  
1297 observed in the data. From `summary()`, the deviance explained by the model is  $\approx 51\%$ .

Figure 9: Graphical diagnostics for the second GAM model. Left: Graphical diagnostics provided by the function `appraise` from the package *gratia*. Right: Fitted smooth for the model, provided by the function `draw`.

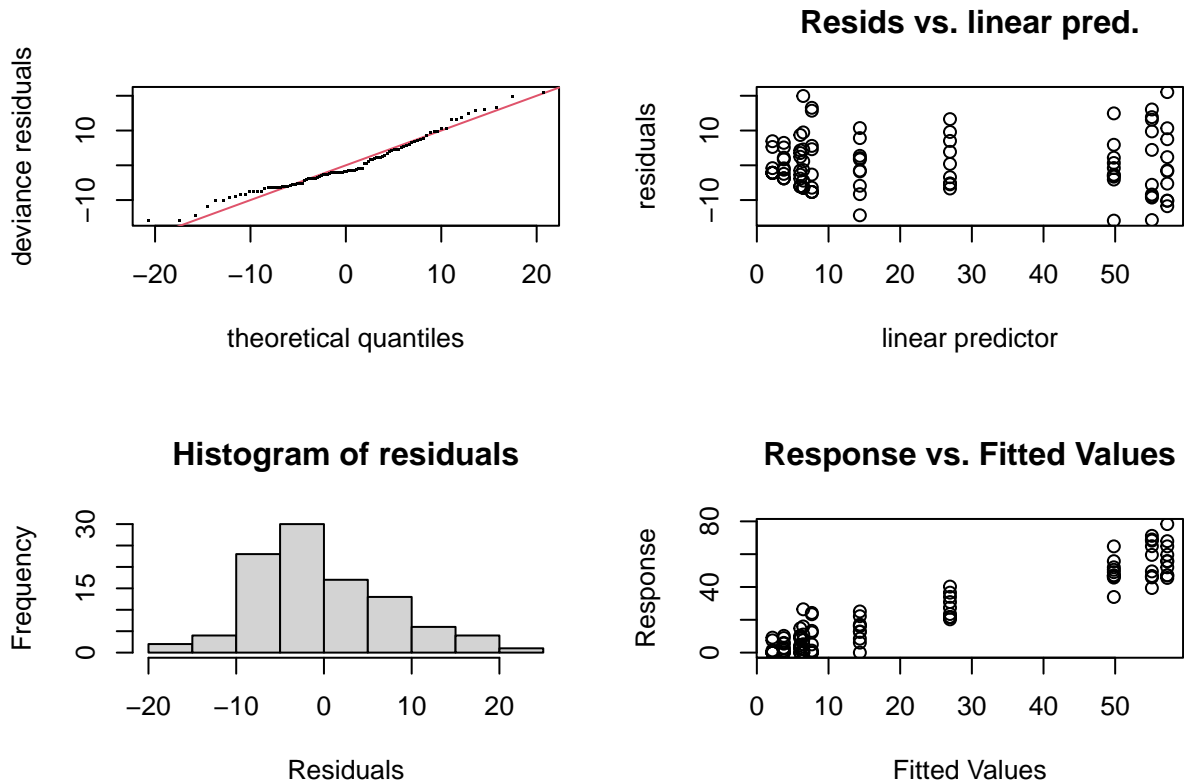

### 1298 B.1.3 Third model

1299 Model `gam_00` was built for didactic purposes to cover the simplest case, but it does not account for the  
1300 nesting of the data by Group, which is apparent from the type of smooth fitted, the model diagnostics, and,  
1301 the low variance explained by the model. On the other hand, `gam_01` takes into account the nesting within  
1302 each group and provides better variance explanation, but as indicated in Section 5, in order to differentiate  
1303 between each group a parametric term needs to be added to the model for the interaction of *Day* and *Group*.

```

1357

```

1358 The resulting model is `m1`, which is the model fitted in the main manuscript. By using `appraise()` and `draw`  
1359 on this model (Figure 10) we see that the trend on the QQ plot has improved, the histogram of the residuals  
1360 appears to be reasonably distributed, and the smooths are capturing the trend of the data within each group.  
1361 From `gam.check`, the k-index is now at an acceptable value ( $\approx 1.02$ ), and `summary` now indicates that the  
1362 model is able to capture 89% of the variance in the data.

Figure 10: Graphical diagnostics for the final GAM model. Left: Graphical diagnostics provided by the function `appraise` from the package *gratia*. Right: Fitted smooths for the model, provided by the function `draw`.

## B.1.4 Comparing models via AIC

One final comparison that can be made for model selection involves the use of the Aikake Information Criterion (AIC). This metric is used to estimate information loss, which we want to minimize with an appropriate model. Therefore, when 2 or more models are compared, the model with lower AIC is preferred. In R, the comparison is done using the `AIC` function.

```
AIC(gam_00, gam_01, m1)
```

	##		df	AIC
	##	gam_00	4.564893	900.8257
	##	gam_01	9.476137	858.6051
	##	m1	10.980983	712.2067

The output in this case is expected: model `m1` has a lower AIC (712.46) whereas the initial two models have higher AICs (900 and 858). The AIC should not be considered as the only estimator of model quality, instead to be used as complimentary information to the graphical diagnostics and model checks described above.

**B.1.4.1 Pairwise comparisons of smooth confidence intervals** The estimation of significant differences between each treatment group can be achieved via pairwise comparisons of the smooth confidence intervals as described in section 5.3. In this case, the “design matrix” is used to estimate the pairwise comparisons (see main manuscript for details and associated references). Briefly, the “design matrix” (also known as the “Xp matrix”) from the selected model (`m1`) is used to calculate a 95% confidence interval of the difference between the smooth terms for each group. This approach allows to estimate the time intervals where a significant difference exists between the groups (confidence interval above or below 0). **All pairwise comparisons in this paper have been centered at the response scale to ease interpretation .**

```
##Pairwise comparisons
pdat <- expand.grid(Day = seq(0, 10, length = 400),
                  Group = c('Control', 'Treatment'))

##matrix that contains the basis functions evaluated at the points in pdat
xp <- predict(m1, newdata = pdat, type = 'lpmatrix')

#Find columns in xp where the name contains "Control"
c1 <- grepl('Control', colnames(xp))

#Find columns in xp where the name contains 'Treatment'
c2 <- grepl('Treatment', colnames(xp))

#Find rows in pdat that correspond to either 'Control' or 'Treatment'
r1 <- with(pdat, Group == 'Control')
r2 <- with(pdat, Group == 'Treatment')

# In xp: find the rows that correspond to Control or Treatment, those that
do not match will be
#set to zero. Then, subtract the values from the rows corresponding
to 'Control' from those that correspond
#to 'Treatment'
X <- xp[r1, ] - xp[r2, ]

## remove columns that do not contain name 'Control' or 'Treatment'
```

```

1416 X[, ! (c1 | c2)] <- 0
1417 ## zero out the parametric cols, those that do not contain in the

```

Figure 11: Smooth pairwise comparisons for model `m1` using a 95% confidence interval for the difference between smooths. The comparison is centered at the response scale. Shaded regions indicate time intervals where each treatment group has a non-zero effect.

Of notice, a convenient wrapper for the function described above exists in the package `gratia`. In this package, `difference_smooths` is a function that makes the comparisons and produces Figure 11 when is

used on a fitted model. The function syntax and an example can be found at:

<https://cran.r-project.org/web/packages/gratia/gratia.pdf>

Keep in mind that this function **does not** center the pairwise comparison at the response scale, so it has to be shifted in order to be compared to the raw data.

## C GAM and Linear model plots and Missing data

This section covers the code used to generate Figure 3, where the simulated data, fit of the “final” GAM (m1), linear model and GAM on data with missing observations are presented. Note that panel A in Figure 3 and the inlet are generated in the code chunk where the data is simulated in Section B, and are called later to build the figure.

### C.1 GAM and Linear model plots

This code chunk creates panels B and D in Figure 3. Note that this code uses the final GAM from the previous section (m1), so the simulated data and the model should be generated before running this section.

```
#linear model
lm1<-lm(St02_sim ~ Day + Group + Day * Group, data = dat_sim)

#creates a dataframe using the length of the covariates for the GAM
gam_predict <- expand_grid(Group = factor(c("Control", "Treatment")),
                          Day = seq(0, 10, by = 0.1),
                          subject=factor(rep(1:10)))

#creates a dataframe using the length of the covariates for rm-ANOVA
lm_predict<-expand_grid(Group = factor(c("Control", "Treatment")),
                        Day = c(0:10),
                        subject=factor(rep(1:10)),
                        )
lm_predict$subject<-factor(paste(lm_predict$subject, lm_predict$Group, sep
= "-"))

#adds the predictions to the grid and creates a confidence interval for
GAM
gam_predict<-gam_predict%>%
  mutate(fit = predict(m1,gam_predict,se.fit = TRUE,type='response')$fit
,
        se.fit = predict(m1, gam_predict,se.fit = TRUE,type='response')
        $se.fit)

#using lm
lm_predict<-lm_predict%>%
  mutate(fit = predict(lm1,lm_predict,se.fit = TRUE,type='response')$fit
,
        se.fit = predict(lm1, lm_predict,se.fit = TRUE,type='response')
        $se.fit)

#plot smooths and confidence interval for GAM
f3<-ggplot(data=dat_sim, aes(x=Day, y=St02_sim, group=Group)) +
```

```

1545     geom_point(aes(color=Group),size=1.5,alpha=0.5,show.legend = FALSE)+
1546     geom_ribbon(aes( x=Day,ymin=(fit - 2*se.fit),
1547                     ymax=(fit + 2*se.fit),

```

## C.2 Working with Missing data in GAMs

This code chunk first randomly deletes 40% of the total observations in the original simulated data, and then an interaction GAM is fitted to the remaining data. Model diagnostics are presented, and an object that stores the fitted smooths is saved to be called in the final code chunk to build the figure.

```
#missing data
#create a sequence of 40 random numbers between 1 and 100, these numbers
  will
#correspond to the row numbers to be randomly erased from the original
  dataset

missing <- sample(1:100, 40)

#create a new dataframe from the simulated data with 40 rows randomly
  removed, keep the missing values as NA

ind <- which(dat_sim$StO2_sim %in% sample(dat_sim$StO2_sim, 40))

#create a new dataframe, remove the StO2 column
dat_missing <- dat_sim[,-1]

#add NAs at the ind positions
dat_missing$StO2_sim[ind]<-NA

#Count the number of remaining observations per day (original dataset had
  10 per group per day)
dat_missing %>%
  group_by(Day,Group) %>%
  filter(!is.na(StO2_sim))%>%
  count(Day)

#the same model used for the full dataset
mod_m1 <- gam(StO2_sim ~ Group+s(Day,by=Group,k=5), data = dat_missing,
  family=scat)
#appraise the model
appraise(mod_m1)

m_predict <- expand_grid(Group = factor(c("Control", "Treatment")),
  Day = seq(0, 10, by = 0.1))

#adds the predictions to the grid and creates a confidence interval
m_predict<-m_predict%>%
  mutate(fit = predict(mod_m1,m_predict,se.fit = TRUE,type='response')$
    fit,
    se.fit = predict(mod_m1, m_predict,se.fit = TRUE,type='response'
    )$se.fit)

f6<-ggplot(data=dat_missing, aes(x=Day, y=StO2_sim, group=Group)) +
  geom_point(aes(color=Group),size=1.5,alpha=0.5,show.legend = FALSE)+
  geom_ribbon(aes( x=Day,ymin=(fit - 2*se.fit),
    ymax=(fit + 2*se.fit),
```

```

1654         fill=Group
1655     ),
1656     alpha=0.3,
1657     data=m_predict,
1658     show.legend=FALSE,
1659     inherit.aes=FALSE) +
1660 geom_line(aes(y=fit,
1661               color=Group),
1662           size=1, data=m_predict,
1663           show.legend = TRUE)+
1664 #facet_wrap(~Group)+
1665 labs(y=expression(atop(StO2[2], 'missing')))+
1666     scale_x_continuous(breaks=c(0,2,5,7,10))+
1667     theme_classic()+
1668 theme(
1669     axis.text=element_text(size=22)
1670 )+
1671     thm+
1672     thm1
1673

```

Figure 12: Simulated data and smooths for oxygen saturation in tumors. A: Simulated data that follows previously reported trends (inset) in tumors under chemotherapy (Treatment) or saline (Control) treatment. Simulated data is from a normal distribution with standard deviation of 10% with 10 observations per time point. Lines indicate mean oxygen saturation B: Smooths from the GAM model for the full simulated data with interaction of Group and Treatment. Lines represent trends for each group, shaded regions are 95% confidence intervals. C: rm-ANOVA model for the simulated data, the model does not capture the changes in each group over time. D: Smooths for the GAM model for the simulated data with 40% of its observations missing. Lines represent trends for each group, shaded regions are 95% confidence intervals.

### C.3 Pairwise comparisons in GAMs: full and missing data cases

The next code chunk reproduces Figure 4. Here pairwise comparisons are made for the full and missing datasets.

```
##Pairwise comparisons

pdat <- expand.grid(Day = seq(0, 10, length = 400),
                  Group = c('Control', 'Treatment'))

#this function takes the model, grid and groups to be compared using the

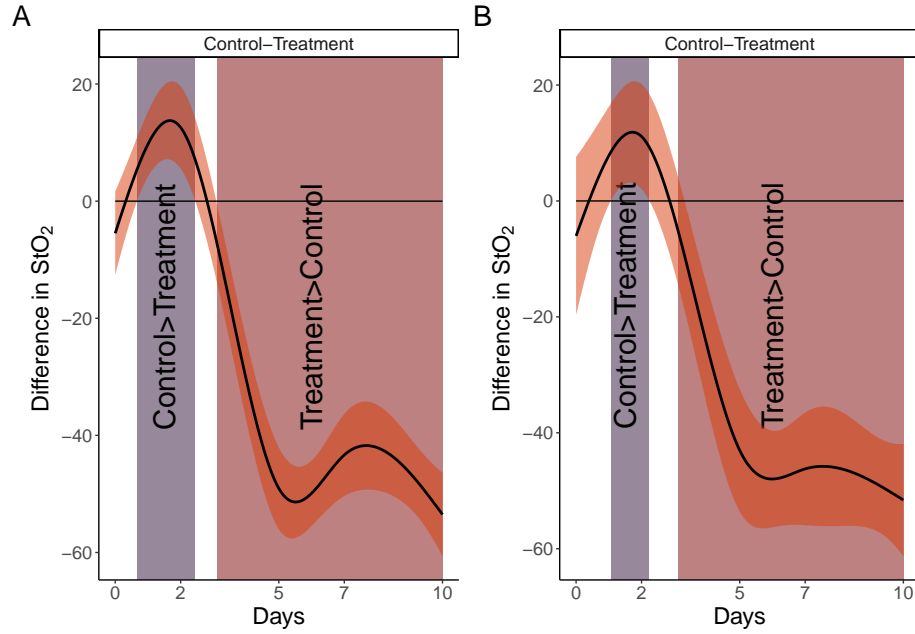

Figure 13: Pairwise comparisons for smooth terms. A: Pairwise comparisons for the full dataset. B: Pairwise comparisons for the dataset with missing observations. Significant differences exist where the interval does not cover 0. In both cases the effect of treatment is significant after day 3.
